

Fundamentals of Python Programming

Introduction to python programming

- High level, interpreted language
- Object-oriented
- General purpose
 - Web development (like: Django and Bottle),
 - Scientific and mathematical computing (Orange, SciPy, NumPy)
 - Desktop graphical user Interfaces (Pygame, Panda3D).

- Other features of python includes the following:
 - Simple language which is easier to learn
 - Free and open source
 - Portability
 - Extensible and embeddable
 - Standard large library

- Created by Guido van Rossum in 1991
- Why the name Python?
 - Not after a dangerous snake.
 - Rossum was fan of a comedy series from late seventies.
 - The name "Python" was adopted from the same series "Monty Python's Flying Circus".

Reasons to Choose Python as First Language

- Simple Elegant Syntax
- Not overly strict
- Expressiveness of the language
- Great Community and Support

Installation of Python in Windows

- Go to Download Python page on the official site (<https://www.python.org/downloads/>) and click Download Python 3.6.5 (You may see different version name)
- When the download is completed, double-click the file and follow the instructions to install it.
- When Python is installed, a program called IDLE is also installed along with it. It provides graphical user interface to work with Python.

- Open IDLE, Write the following code below and press enter.

```
print("Hello, World!")
```

- To create a file in IDLE, go to File > New Window (Shortcut: Ctrl+N).
- Write Python code and save (Shortcut: Ctrl+S) with .py file extension like: hello.py or your-first-program.py

```
print("Hello, World!")
```

- Go to Run > Run module (Shortcut: F5) and you can see the output.

First Python Program

AddTwoNumber.py · C:\Users\hp\AppData\Local\Programs\Python\Python36-32\Scripts\AddTwoNumber.py (3.6.5)

- □ X

Few Important Things to Remember

- To represent a statement in Python, newline (enter) is used.
- Use of semicolon at the end of the statement is optional (unlike languages like C/C++)
- In fact, it's recommended to omit semicolon at the end of the statement in Python
- Instead of curly braces { }, indentations are used to represent a block

Python Keywords

- Keywords are the reserved words(can not be used as a identifier) in Python
- Are case sensitive

Keywords in Python programming language

False	class	finally	is	return
None	continue	for	lambda	try
True	def	from	nonlocal	while
and	del	global	not	with
as	elif	if	or	yield
assert	else	import	pass	
break	except	in	raise	

Python Identifiers

- Name given to entities like class, functions, variables etc. in Python
- Rules for writing identifiers
 - Can be a combination of letters in lowercase (a to z) or uppercase (A to Z) or digits (0 to 9) or an underscore (_)
 - myClass, var_1 and print_this_to_screen, all are valid examples
 - Cannot start with a digit
 - 1variable is invalid, but variable1 is perfectly fine
 - Keywords cannot be used as identifiers
 - Cannot use special symbols like !, @, #, \$, % etc. in our identifier
 - Can be of any length.

Things to care about

- Python is a case-sensitive language.
 - Variable and variable are not the same.
- Multiple words can be separated using an underscore, `this_is_a_long_variable`
- Can also use camel-case style of writing, i.e., capitalize every first letter of the word except the initial word without any spaces
 - `camelCaseExample`

Python Statement

- Instructions that a Python interpreter can execute are called statements.
- Two types
 - Single line statement:
 - For example, `a = 1` is an assignment statement
 - Multiline statement:
 - In Python, end of a statement is marked by a newline character.
 - So, how to make multiline statement?

- Technique1:

- make a statement extend over multiple lines with the line continuation character (\).
- For example:

```
a = 1 + 2 + 3 + \
```

```
4 + 5 + 6 + \
```

```
7 + 8 + 9
```

- Technique2:

- make a statement extend over multiple lines with the parentheses ()
- For example:

```
a = (1 + 2 + 3 +  
    4 + 5 + 6 +  
    7 + 8 + 9)
```

- Technique3:

- make a statement extend over multiple lines with the brackets [] and braces { }.
- For example:

```
colors = ['red',  
          'blue',  
          'green']
```

- We could also put multiple statements in a single line using semicolons, as follows

```
a = 1; b = 2; c = 3
```

Python Indentation

- Most of the programming languages like C, C++, Java use braces { } to define a block of code
- Python uses indentation
- A code block (body of a function, loop etc.) starts with indentation and ends with the first un-indented line

Indenttion.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/Indenttion.py (3.6.5) — □ X

Python Comments

- To make the code much more readable.
- Python Interpreter ignores comment.
- Two types of comment is possible in python:
 - Single line comment and
 - Multi-line comment

Single line comment

- In Python, we use the hash (#) symbol to start writing a comment.
- It extends up to the newline character

The screenshot shows a window titled "SingleLineComment.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/SingleLineComment.py (3.6.5)". The menu bar includes "File", "Edit", "Format", "Run", "Options", "Window", and "Help". The code editor contains the following text:

```
#This is a comment

#print out Hello

print("Hello")
```

Multi-line comments

- Two way:

- By using # sign at the beginning of each line

```
#This is a long comment
```

```
#and it extends
```

```
#to multiple lines
```

- By using either ' ' ' or " " " (most common)

```
"""This is also a
```

```
perfect example of
```

```
multi-line comments"""
```

Python Variable

- a variable is a named location used to store data in the memory.
- Alternatively, variables are container that hold data which can be changed later throughout programming

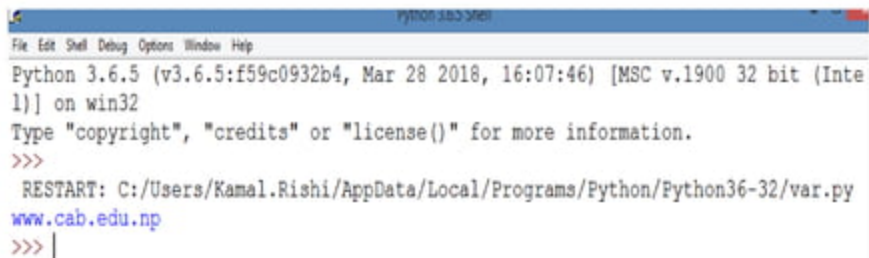

Declaring Variables

- In Python, variables do not need declaration to reserve memory space.
- The "variable declaration" or "variable initialization" happens automatically when we assign a value to a variable.
- We use the assignment operator = to assign the value to a variable.

Assigning Values to variables

A screenshot of a Python IDE window. The title bar shows the file path 'var.py - C:/Users/Kamal.Rishi/AppData/Local/Programs/Python/Python36-32/var.py (3.6.5)'. The menu bar includes 'File', 'Edit', 'Format', 'Run', 'Options', 'Window', and 'Help'. The code editor contains three lines of Python code: a red comment line '#Declaring and assigning value to the variables', a green line 'website="www.cab.edu.np"', and a purple line 'print(website)|'.

```
var.py - C:/Users/Kamal.Rishi/AppData/Local/Programs/Python/Python36-32/var.py (3.6.5)
File Edit Format Run Options Window Help
#Declaring and assigning value to the variables
website="www.cab.edu.np"
print(website)|
```

A screenshot of a Python 3.6.5 Shell window. The title bar is blue and says "python 3.6.5 Shell". The menu bar is light gray and contains "File", "Edit", "Shell", "Debug", "Options", "Window", and "Help". The main text area is white and contains the following text: "Python 3.6.5 (v3.6.5:f59c0932b4, Mar 28 2018, 16:07:46) [MSC v.1900 32 bit (Intel)] on win32", "Type 'copyright', 'credits' or 'license()' for more information.", a red prompt ">>>", the text "RESTART: C:/Users/Kamal.Rishi/AppData/Local/Programs/Python/Python36-32/var.py", the URL "www.cab.edu.np" in blue, and another red prompt ">>>" followed by a vertical cursor bar.

```

Rules and Naming convention for variables and constants

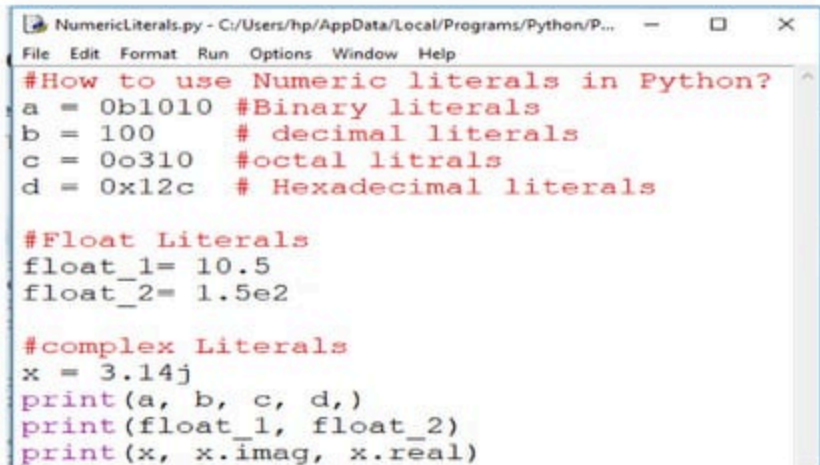

- Create a name that makes sense. Suppose, vowel makes more sense than v.
- Use camelCase notation to declare a variable
- For example: myName, myAge, myAddress
- Use capital letters where possible to declare a constant
- For example: PI, G, MASS etc.

- Never use special symbols like !, @, #, \$, %, etc.
- Don't start name with a digit.
- Constants are put into Python modules
- Constant and variable names should have combination of letters in lowercase (a to z) or uppercase (A to Z) or digits (0 to 9) or an underscore (_).
- For example: snake_case, MACRO_CASE, camelCase, CapWords

Literals

- Literal is a raw data given in a variable or constant. In Python, there are various types of literals they are as follows:
- Numeric literals
- String literals
- Boolean literals
- Special literals

Numeric Literals

```
NumericLiterals.py - C:/Users/hp/AppData/Local/Programs/Python/P...
File Edit Format Run Options Window Help
#How to use Numeric literals in Python?
a = 0b1010 #Binary literals
b = 100    # decimal literals
c = 0o310  #octal literals
d = 0x12c  # Hexadecimal literals

#Float Literals
float_1= 10.5
float_2= 1.5e2

#complex Literals
x = 3.14j
print(a, b, c, d,)
print(float_1, float_2)
print(x, x.imag, x.real)
```

A screenshot of a Windows command prompt window titled "Python 3.6.5 Shell". The window has a standard menu bar with "File", "Edit", "Shell", "Debug", "Options", "Window", and "Help". The text inside the window shows the Python version and build information, followed by a prompt to type "copyright", "credits", or "license()". Then, the command "RESTART: C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/NumericLiterals.py" is entered, and its output is displayed: "10 100 200 300", "10.5 150.0", and "3.14j 3.14 0.0". The prompt ">>>" is followed by a vertical bar cursor.

```
Python 3.6.5 (v3.6.5:f59c0932b4, Mar 28 2018, 16:07:46) [MSC v.1900 32 bit (Intel)] on win32
Type "copyright", "credits" or "license()" for more information.

>>> dict([1,'one'],[2,'two'],[3,'three'])
{1: 'one', 2: 'two', 3: 'three'}
>>> |
```

Python Type Conversion and Type Casting

- The process of converting the value of one data type (integer, string, float, etc.) to another data type is type conversion
- Python has two types of type conversion.
 - Implicit Type Conversion
 - Explicit Type Conversion

- Type Conversion is the conversion of object from one data type to another data type
- Implicit Type Conversion is automatically performed by the Python interpreter
- Python avoids the loss of data in Implicit Type Conversion
- Explicit Type Conversion is also called Type Casting, the data types of object are converted using predefined function by user
- In Type Casting loss of data may occur as we enforce the object to specific data type

Implicit Type Conversion

- Automatically converts one data type to another data type
- Always converts smaller data type to larger data type to avoid the loss of data

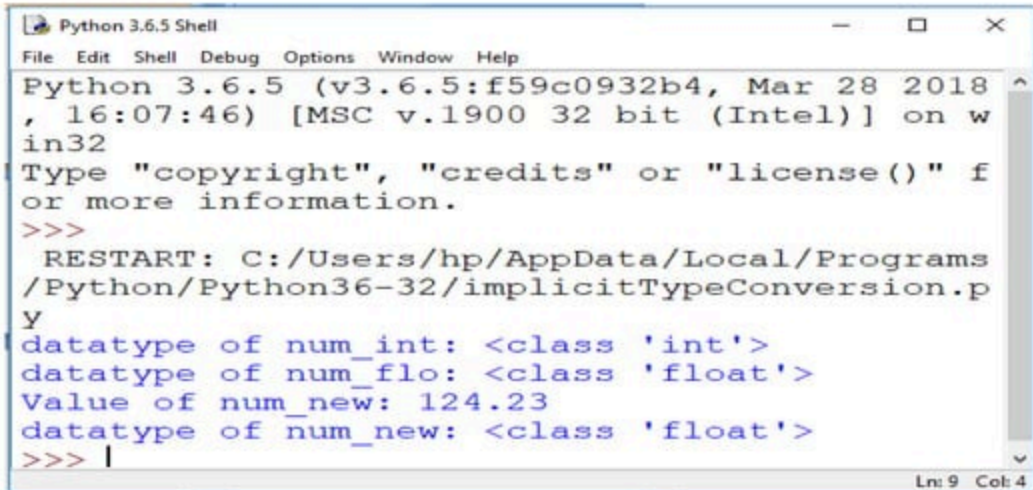

```
implicitTypeConversion.py - C:/Users/hp/AppData/Local/Programs/Python...
File Edit Format Run Options Window Help
#Implicit type conversion
#Converting integer to float
num_int = 123
num_flo = 1.23

num_new = num_int + num_flo

print("datatype of num_int:",type(num_int))
print("datatype of num_flo:",type(num_flo))

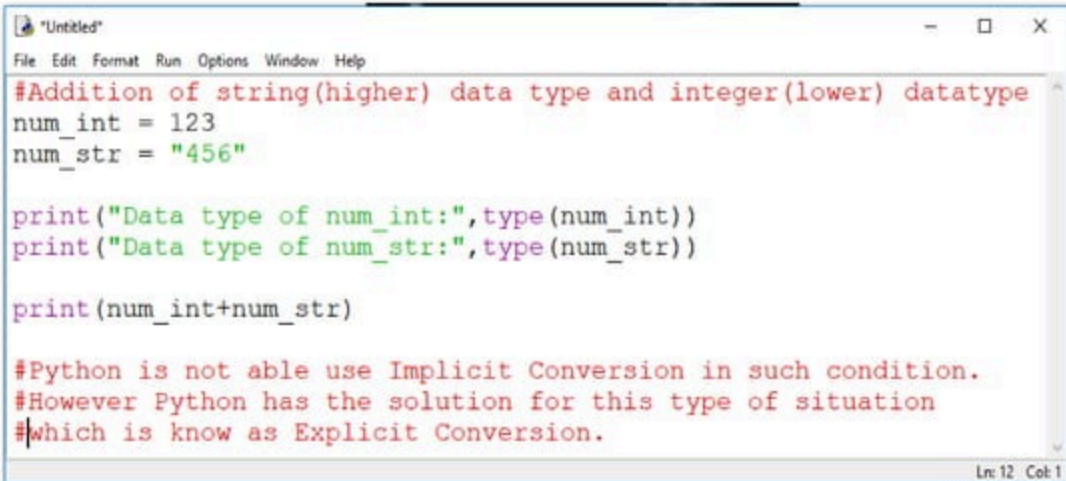

print("Value of num_new:",num_new)
print("datatype of num_new:",type(num_new))
```

Ln: 1 Col: 25

A screenshot of a Windows command prompt window titled "Python 3.6.5 Shell". The window has a menu bar with "File", "Edit", "Shell", "Debug", "Options", "Window", and "Help". The main text area shows the Python 3.6.5 startup banner, including the version, build number (f59c0932b4), date (Mar 28 2018), time (16:07:46), and architecture (MSC v.1900 32 bit (Intel) on win32). It prompts the user to type "copyright", "credits", or "license()" for more information. The user has entered three greater-than signs (>>>), which has triggered a restart of the interpreter. The restart message shows the current file path: C:/Users/hp/AppData/Local/Programs/Python/Python36-32/implicitTypeConversion.py. Below the restart message, the interpreter displays the datatypes for num_int (int), num_flo (float), and num_new (float), along with the value of num_new (124.23). The prompt >>> is followed by a vertical bar character (|). The status bar at the bottom right indicates "Ln: 9 Col: 4".

Explicit Type Conversion

- Users convert the data type of an object to required data type.
- Predefined functions like `int()`, `float()`, `str()`, etc. are to perform explicit type conversion
- Is also called typecasting because the user casts (change) the data type of the objects.
- Syntax :
 - `(required_datatype)(expression)`
 - `Int(b)`

Example

The screenshot shows a Python IDE window titled "explicitTypeConversion.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/explicitTypeConversion.py (3.6.5)". The menu bar includes File, Edit, Format, Run, Options, Window, and Help. The code in the editor is as follows:

```
#Addition of string and integer using explicit conversion
num_int = 123
num_str = "456"

print("Data type of num_int:", type(num_int))
print("Data type of num_str before Type Casting:", type(num_str))

num_str = int(num_str)
print("Data type of num_str after Type Casting:", type(num_str))

num_sum = num_int + num_str

print("Sum of num_int and num_str:", num_sum)
print("Data type of the sum:", type(num_sum))
```

The status bar at the bottom right indicates "Ln: 1 Col: 57".

```

Sum of num_int and num_str: 579
Data type of the sum: <class 'int'>
>>> |
```

Lni: 10 Col: 4

Python Input, Output and Import

- Widely used functions for standard input and output operations are:
 - `print()` and
 - `input()`

Python Output Using print() function

```
printFunction.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/...
File Edit Format Run Options Window Help
#program to illustrate the print()function
print('This sentence is output to the screen')
# Output: This sentence is output to the screen
a = 5
print('The value of a is', a)
# Output: The value of a is 5
Ln: 10 Col: 0
```

```
This sentence is output to the screen
The value of a is 5
>>> |
```

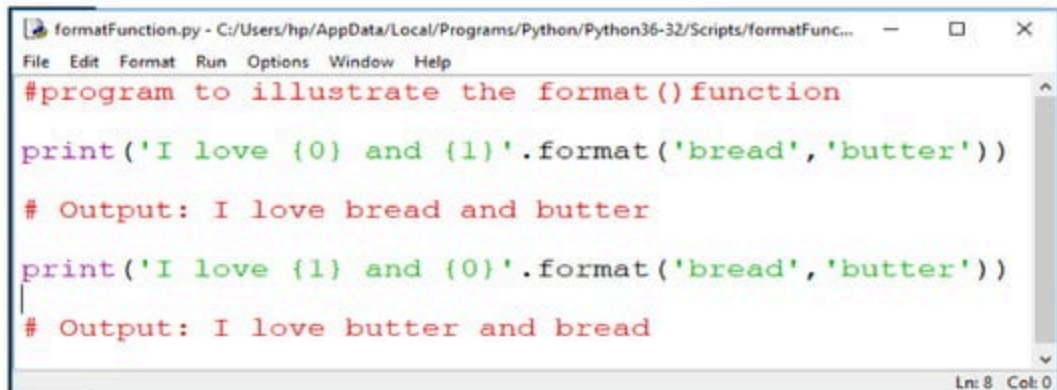

Output formatting

- Can be done by using the `str.format()` method
 - Is visible to any string object

```
>>> x = 5; y = 10
>>> print('The value of x is {} and y is {}'.format(x,y))
The value of x is 5 and y is 10
>>> |
```

- Here the curly braces `{}` are used as placeholders. We can specify the order in which it is printed by using numbers (tuple index).

Example

The screenshot shows a window titled "formatFunction.py" with a menu bar (File, Edit, Format, Run, Options, Window, Help). The code inside is as follows:

```
#program to illustrate the format() function

print('I love {0} and {1}'.format('bread', 'butter'))

# Output: I love bread and butter

print('I love {1} and {0}'.format('bread', 'butter'))
|
# Output: I love butter and bread
```

The status bar at the bottom right indicates "Ln: 8 Col: 0".

```
I love bread and butter
I love butter and bread
>>> |
```

- We can even use keyword arguments to format the string

```
>>> print('Hello {name}, {greeting}'.format(greeting = 'Goodmorning', name = 'Ram'))  
Hello Ram, Goodmorning  
>>> |
```

- We can even format strings like the old printf() style used in C
- We use the % operator to accomplish this

```
>>> x= 12.3456789
>>> print('the value of x is %3.2f' %x)
the value of x is 12.35
>>> print('the value of x is %3.3f' %x)
the value of x is 12.346
>>> |
```

Input() function

- input() function to take the input from the user.
- The syntax for input() is :
 - input([prompt])
 - where prompt is the string we wish to display on the screen.
 - It is optional

```
>>> num = input('Enter a number: ')
Enter a number: 10
>>> num
'10'
>>> |
```

- Entered value 10 is a string, not a number.
- To convert this into a number we can use int() or float() functions

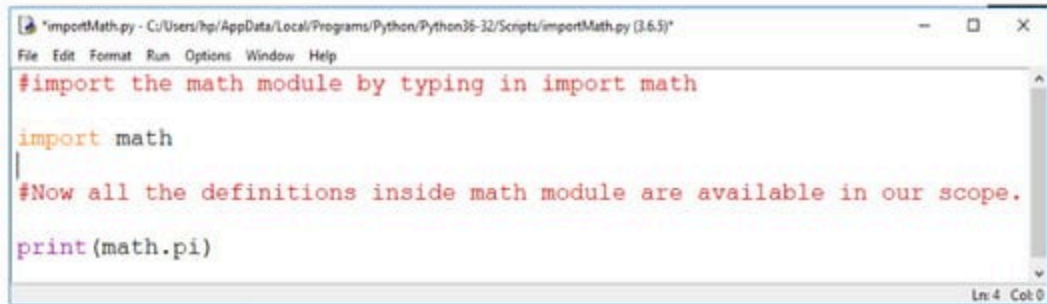

```
>>> int('10')
10
>>> float('10')
10.0
>>> |
```

- This same operation can be performed using the eval(). It can evaluate expressions, provided the input is a string.

```
>>> int('2+3')
Traceback (most recent call last):
  File "<pyshell#9>", line 1, in <module>
    int('2+3')
ValueError: invalid literal for int() with base 10: '2+3'
>>> eval('2+3')
5
>>> |
```

Python Import

- When our program grows bigger, it is a good idea to break it into different modules.
- A module is a file containing Python definitions and statements.
- Python modules have a filename and end with the extension .py
- Definitions inside a module can be imported to another module or the interactive interpreter in Python
- We use the import keyword to do this

```
*importMath.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/importMath.py (3.6.5)*
File Edit Format Run Options Window Help
#import the math module by typing in import math
import math
|
#Now all the definitions inside math module are available in our scope.
print(math.pi)
Ln: 4 Col: 0
```

3.141592653589793

>>> |

- import some specific attributes and functions only, using the from keyword.

```
>>> from math import pi
>>> pi
3.141592653589793
>>> |
```

Python Operators

- Operators are special symbols in Python that carry out arithmetic or logical computation.
- The value that the operator operates on is called the operand.
- For example:

```
>>> 2+3  
5
```

- Here, + is the operator that performs addition.
- 2 and 3 are the operands and 5 is the output of the operation.

Arithmetic operators

Arithmetic operators in Python

Operator	Meaning	Example
+	Add two operands or unary plus	$x + y$ +2
-	Subtract right operand from the left or unary minus	$x - y$ -2
*	Multiply two operands	$x * y$
/	Divide left operand by the right one (always results into float)	x / y
%	Modulus - remainder of the division of left operand by the right	$x \% y$ (remainder of x/y)
//	Floor division - division that results into whole number adjusted to the left in the number line	$x // y$
**	Exponent - left operand raised to the power of right	$x ** y$ (x to the power y)

Example

```
arithmeticOperator.py - C:/Users/hp/AppData/Loc...
File Edit Format Run Options Window Help
# Arithmetic operators in Python
x = 15
y = 4

# Output: x + y = 19
print('x + y =', x+y)

# Output: x - y = 11
print('x - y =', x-y)

# Output: x * y = 60
print('x * y =', x*y)

# Output: x / y = 3.75
print('x / y =', x/y)

# Output: x // y = 3
print('x // y =', x//y)

# Output: x ** y = 50625
print('x ** y =', x**y)
```

Ln: 1 Col: 32

x + y = 19
x - y = 11
x * y = 60
x / y = 3.75
x // y = 3
x ** y = 50625

Comparison operators

Comparison operators in Python

Operator	Meaning	Example
>	Greater than - True if left operand is greater than the right	<code>x > y</code>
<	Less than - True if left operand is less than the right	<code>x < y</code>
==	Equal to - True if both operands are equal	<code>x == y</code>
!=	Not equal to - True if operands are not equal	<code>x != y</code>
>=	Greater than or equal to - True if left operand is greater than or equal to the right	<code>x >= y</code>
<=	Less than or equal to - True if left operand is less than or equal to the right	<code>x <= y</code>

```
comparisionOperator.py - C:/Users/hp/AppData/Local...
File Edit Format Run Options Window Help
#Comparison operators in Python
x = 10
y = 12

# Output: x > y is False
print('x > y is',x>y)

# Output: x < y is True
print('x < y is',x<y)

# Output: x == y is False
print('x == y is',x==y)

# Output: x != y is True
print('x != y is',x!=y)

# Output: x >= y is False
print('x >= y is',x>=y)

# Output: x <= y is True
print('x <= y is',x<=y)

Ln: 1 Col: 31
```

x > y is False
x < y is True
x == y is False
x != y is True
x >= y is False
x <= y is True

Logical operators

Logical operators in Python

Operator	Meaning	Example
and	True if both the operands are true	x and y
or	True if either of the operands is true	x or y
not	True if operand is false (complements the operand)	not x

```
LogicalOperator.py - C:/Users/hp/AppDat...
File Edit Format Run Options Window Help

#Logical Operators in Python
x = True
y = False

# Output: x and y is False
print('x and y is',x and y)

# Output: x or y is True
print('x or y is',x or y)

# Output: not x is False
print('not x is',not x)

Ln: 1 Col: 28
```

x and y is False
x or y is True
not x is False

Bitwise operators

- Bitwise operators act on operands as if they were string of binary digits. It operates bit by bit, hence the name.
- For example, 2 is 10 in binary and 7 is 111.
- In the table below: Let $x = 10$ (0000 1010 in binary) and $y = 4$ (0000 0100 in binary)

Bitwise operators in Python

Operator	Meaning	Example
&	Bitwise AND	$x \& y = 0$ (0000 0000)
	Bitwise OR	$x y = 14$ (0000 1110)
~	Bitwise NOT	$\sim x = -11$ (1111 0101)
^	Bitwise XOR	$x \wedge y = 14$ (0000 1110)
>>	Bitwise right shift	$x >> 2 = 2$ (0000 0010)
<<	Bitwise left shift	$x << 2 = 40$ (0010 1000)

Assignment operators

- Assignment operators are used in Python to assign values to variables.
- `a = 5` is a simple assignment operator that assigns the value 5 on the right to the variable `a` on the left.
- There are various compound operators in Python like `a += 5` that adds to the variable and later assigns the same.
- It is equivalent to `a = a + 5`.

Assignment operators in Python

Operator	Example	Equivalent to
=	x = 5	x = 5
+=	x += 5	x = x + 5
-=	x -= 5	x = x - 5
*=	x *= 5	x = x * 5
/=	x /= 5	x = x / 5
%=	x %= 5	x = x % 5
//=	x //= 5	x = x // 5
**=	x **= 5	x = x ** 5
&=	x &= 5	x = x & 5
=	x = 5	x = x 5
^=	x ^= 5	x = x ^ 5
>>=	x >>= 5	x = x >> 5
<<=	x <<= 5	x = x << 5

Special operators

- identity operator
- membership operator

Identity operators

- is and is not are the identity operators in Python.
- They are used to check if two values (or variables) are located on the same part of the memory.
- Two variables that are equal does not imply that they are identical.

Identity operators in Python

Operator	Meaning	Example
is	True if the operands are identical (refer to the same object)	x is True
is not	True if the operands are not identical (do not refer to the same object)	x is not True

```
*specialOperator.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/specialOperator.py (3.6.3)*
File Edit Format Run Options Window Help

#Identity operators in Python
#x1 and y1 are integers of same values,
#so they are equal as well as identical.
#Same is the case with x2 and y2 (strings).
x1 = 5
y1 = 5
x2 = 'Hello'
y2 = 'Hello'
#But x3 and y3 are list. They are equal but not identical.
#Since list are mutable (can be changed),
#interpreter locates them separately in memory although they are equal.
x3 = [1,2,3]
y3 = [1,2,3]

# Output: False
print(x1 is not y1)

# Output: True
print(x2 is y2)

# Output: False
print(x3 is y3)
```

False
True
False

Membership operators

- in and not in are the membership operators in Python
- They are used to test whether a value or variable is found in a sequence (string, list, tuple, set and dictionary).
- In a dictionary we can only test for presence of key, not the value

Operator	Meaning	Example
in	True if value/variable is found in the sequence	5 in x
not in	True if value/variable is not found in the sequence	5 not in x

```
*Untitled*
File Edit Format Run Options Window Help
#Membership operators in Python
x = 'Hello world'
y = {1:'a',2:'b'}

# Output: True
print('H' in x)

# Output: True
print('hello' not in x)

# Output: True
print(1 in y)

# Output: False
print('a' in y)

Ln: 16 Col: 0
```

True
True
True
False

Python Namespace and Scope

- Name (also called identifier) is simply a name given to objects.
- Everything in Python is an object
- Name is a way to access the underlying object.
- For example:
 - when we do the assignment `a = 2`, here 2 is an object stored in memory and a is the name we associate it with
 - We can get the address (in RAM) of some object through the built-in function, `id()`

```
objectId.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/...  
File Edit Format Run Options Window Help  
# Note: You may get different value of id  
  
a = 2  
# Output: id(2) = 1706877728  
print('id(2) =', id(2))  
  
# Output: id(a) = 1706877728  
print('id(a) =', id(a))  
# Here, both refer to the same object.  
|
```

Ln: 9 Col: 37

id(2) = 1706877728
id(a) = 1706877728

```
#Program to illustrate dynamic nature of name binding in python
#Python doesn't have to create a new duplicate object

# Note: You may get different value of id

a = 2 #an object 2 is created and the name a is associated with it

# Output: id(a) = 1706877728
print('id(a) =', id(a))

a = a+1      #a new object 3 is created and now a associates with this object.

# Output: id(a) = 1706877744
print('id(a) =', id(a))

# Output: id(3) = 1706877744
print('id(3) =', id(3))

b = 2      # the new name b gets associated with the previous object 2.

# Output: id(2) = 1706877728
print('id(2) =', id(2))
```

a = 2

a = a + 1

b = 2

A name could refer to any type of object

```
>>> a = 5
>>> print(a)
5
>>> a = "Hello World!"
>>> print(a)
Hello World!
>>> a = [1, 2, 3]
>>> print(a)
[1, 2, 3]
>>> |
```

Functions are objects too, so a name can refer to them as well

hello.py - C:/Users/Cab/AppData/Local/Programs/Python/Python36/hello.py (3.6.3)

File Edit Format Run Options Window Help

```
def hello_function():  
    print("Hello")  
hello_function()  
a=hello_function  
a()  
|
```

Hello
Hello

What is a Namespace in Python?

- namespace is a collection of names.
- Help to eliminate naming collision/naming conflict

- A namespace containing all the built-in names is created when we start the Python interpreter and exists as long we don't exit
- Each module creates its own global namespace
- Modules can have various user defined functions and classes.
- A local namespace is created when a function is called, which has all the names defined in it.
- Similar, is the case with class

Built-in Namespace

Module: Global Namespace

Function: Local Namespace

Python Variable Scope

- All namespaces may not be accessible from every part of the program
- Scope is the portion of the program from where a namespace can be accessed directly without any prefix

- At any given moment, there are at least three nested scopes.
- Scope of the current function which has local names
- Scope of the module which has global names
- Outermost scope which has built-in names
- When a reference is made inside a function, the name is searched in the local namespace, then in the global namespace and finally in the built-in namespace.
- If there is a function inside another function, a new scope is nested inside the local scope.

#Example of Scope and Namespace in Python

def outer_function():

 b = 20 # b is in local namespace of outer_function

 def inner_func():

 c = 30 #c is in local namespace of inner_function

 #c is local so we can read and reassign value to c

 #a is global and b in non-local here so read only

 # reassignment to a and b creates new variables a and b in this scope

a = 10 # in global namespace

```
*scope2.py - C:/Users/hp/AppData/Local/Programs/Python/Python36-32/Scripts/scope2.py...
File Edit Format Run Options Window Help

#Three different variables a are defined in
#separate namespaces and accessed accordingly.
def outer_function():
    a = 20
    def inner_function():
        a = 30
        print('a =', a)

    inner_function()
    print('a =', a)

a = 10
outer_function()
print('a =', a)
```

Ln: 1 Col: 2

```
a = 30
a = 20
a = 10
```

```
